ABSTRACT

Accurate prediction of viscosity (η) at high pressures (P) necessitates an extremely reliable force field for at least two reasons. First, the viscosity at a given density (ρ) is highly sensitive to the function form and associated parameters, especially those of the non-bonded interactions. Second, the viscosity depends strongly on the predicted density, which is also very sensitive to the force field.

To develop a highly accurate force field, the CH₃, CH₂, CH, and C non-bonded parameters are optimized simultaneously using a large data set. Since the challenge compound is 2,2,4-trimethylhexane (TMH), we chose 2,2,4-trimethylpentane (TMP, a.k.a. isooctane) as a surrogate molecule to improve transferability. Specifically, the optimal non-bonded parameters are obtained empirically by minimizing the deviation between the predicted and REFPROP $P\rho T$ and caloric properties for TMP over a wide range of state points, with particular emphasis at high pressures.

An essential aspect of the challenge is to provide meaningful estimates of uncertainty. For this reason, uncertainties in the predicted TMH viscosity are quantified using three different methods. First, we estimate systematic bias in the force field by comparing the simulated and REFPROP η values for the surrogate compound, TMP, at the challenge temperature and pressures. Second, we account for the uncertainty in η that is associated with uncertainties in ρ for a given P. Third, we propagate the uncertainty in the force field non-bonded parameters using Bayesian inference.
